Singlet O₂ Production from Photoexcited NO₂

Theodore Frankiewicz¹ and R. Stephen Berry

Department of Chemistry and The James Franck Institute, The University of Chicago, Chicago, IL 60637

■ Mixtures of NO₂ and O₂ were irradiated with visible light. ($\lambda > 4000\text{\AA}$). Electronically excited NO₂ was produced which transferred energy collisionally to O₂ to produce O₂(¹Δ_g). The population of O₂(¹Δ_g) in the reaction cell was determined by monitoring its phosphorescent emission at 1.27 μ with an RCA 7102 photomultiplier used in a photon-counting mode. From the experimentally determined rate of production and destruction of O₂(¹Δ_g), the probability that a quenching collision of NO₂* with O₂ will produce O₂(¹Δ_g) is found to be $\alpha = 0.01 \pm 0.002$. This mechanism is capable of producing a steady-state O₂(¹Δ_g) concentration in the atmosphere of 10⁻⁷–10⁻⁸ cm⁻³.

The possibility that singlet molecular oxygen might play a noticeable role in the photochemical smog cycle was pointed out by Pitts (1969). Herron and Huie (1969) found the relative reactivities of single molecular oxygen, oxygen atom, and ozone to be 10⁻³:1:1 at best and concluded that known mechanisms for producing metastable O₂ molecules were not sufficiently effective to make these species important in the smog cycle. Subsequent work indicates the reactivity ratio may be more like 10⁻⁴:1:1 (Johnston et al., 1971). About the same time, Kummler and Bortner (1969), Steer et al. (1969b), and Snelling (1968) showed that benzaldehyde, benzene, naphthalene, and naphthalene derivatives

could absorb light and transfer this energy to O₂ to produce excited oxygen molecules. Still, these mechanisms seem too inefficient to be important for smog formation because of the low ambient concentrations of the photosensitizing species and their small extinction coefficients in the visible or near-uv spectral regions.

We have investigated another possible mechanism for generating singlet molecular oxygen, the production of O₂(¹Δ) by the NO₂-photosensitized process

This process was studied by irradiation of NO₂-O₂ mixtures with a chopped, carefully filtered beam of visible light. Wavelengths below 4000 Å were excluded to avoid photodissociation of the NO₂ (Douglas and Huber, 1965; Schuck et al., 1966; Cvetanovic, 1964). Direct measurement of the 1.27-μ emission from the process O₂(¹Δ) → O₂(³Σ) + hν was used to monitor the energy transfer. Emission was observed through two Corning No. 7-56 filters with an RCA 7102 photomultiplier operated as a photon counter. The emission was confirmed as originating only at 1.27 μ by scanning the line with a temperature-tuned, narrow band interference filter (Razdow Optical Instruments, 1.2728 μ peak transmission at 20°C). The photomultiplier tube was calibrated against a blackbody source with various filter combinations. Under our operating conditions, the quantum efficiency of the tube at 1.27 μ is 1.5 × 10⁻⁷. The observed signal was about 4 counts/sec. Modulation at 30 Hz was as follows: The sample was irradiated during the first 1/4 cycle; after 1/8-cycle delay, the photomultiplier

¹ To whom correspondence should be addressed.

was gated on for $1/2$ cycle, the final $1/8$ cycle was dead time.

The pressure dependence of both the near-ir and visible NO_2 emission gave Stern-Volmer plots which yielded values for NO_2 quenching by N_2 and by O_2 in essential agreement with those in the literature (Meyers et al., 1966; Schwartz, 1968).

In a typical experiment, $p(\text{NO}_2) \cong 0.48$ torr, $p(\text{O}_2) \cong 3.0$ torr, and the system absorbs approximately 5.4×10^{15} photons/sec, all in the wavelength range 4000–5000Å. From geometric factors and the observed rate of emission by $\text{O}_2(^1\Delta)$, we estimated a total $\text{O}_2(^1\Delta)$ production rate of 4.1×10^{13} /sec. These diffuse uniformly throughout a cell of 860 cm^3 , in the irradiation interval. Deactivation of excited O_2 molecules is due to wall collisions, to collisions with NO_2 , to collisions with O_2 and, in very small part, to radiation. The pseudo first-order rate coefficients for the first three processes are 0.10 sec^{-1} (in our system), 0.08 sec^{-1} , and 0.21 sec^{-1} , respectively (Becker et al., 1971; Steer et al., 1969a); the radiative rate is $2.58 \times 10^{-4} \text{ sec}^{-1}$. The system is in a steady state with respect to $\text{O}_2(^1\Delta)$, with an effective total first-order decay constant of 0.39 sec^{-1} .

From the known quenching constants (Meyers et al., 1966; Schwartz, 1968) for NO_2^* by NO_2 ($7.1 \times 10^{-11} \text{ cm}^3/\text{mol-sec}$), the measured concentrations of NO_2 and O_2 , and the knowledge that NO_2 fluorescence is completely quenched, we determine that fraction of photons absorbed which go one way or another to O_2 . From the experimentally determined rate of production (and destruction) of $\text{O}_2(^1\Delta)$, we thus determine the probability, α , that a quenching collision of NO_2^* with O_2 will produce $\text{O}_2(^1\Delta)$:

$$\alpha = 0.01 \pm 0.002 \quad (3)$$

The uncertainty is due largely to uncertainties in collection efficiency from molecules away from the optic axis of the photomultiplier. In other words, about 1% of the collisions of NO_2^* with O_2 yield a metastable $\text{O}_2(^1\Delta)$.

The possible significance of this observation for the problem of smog appears when we estimate the ambient concentration of $\text{O}_2(^1\Delta)$ from the NO_2 -activated process alone. The rate constant for quenching of NO_2^* by N_2 is $3.1 \times 10^{-11} \text{ cm}^3/\text{mol-sec}$, slightly less than that for quenching by O_2 . From these two coefficients, we infer that about 21.5% of the NO_2^* in the atmosphere lose their energy to O_2 , and thus about 0.215% of the excited NO_2^* molecules generate $\text{O}_2(^1\Delta)$. (NO_2 fluorescence is, of course, completely quenched in the atmosphere.) The rate of production of NO_2^* by light in the 4000–5000Å region, when the NO_2 concentration is 0.035 ppm and the photon flux in the 4000–5000Å interval is $5 \times 10^{16}/\text{cm}^2\text{-sec}$ —corresponding to the sun 40° from the zenith, on a clear day—is about $2.3 \times 10^{10}/\text{cm}^3\text{-sec}$. Hence the rate of production of $\text{O}_2(^1\Delta)$ under these conditions is about $4.35 \times 10^7/\text{cm}^3\text{-sec}$. The $\text{O}_2(^1\Delta)$ is in a steady-state condition, with most of its quenching accomplished by O_2 ; the rate coefficient for this process is $2.2 \times 10^{-18} \text{ cm}^3/\text{mol-sec}$. Hence the pseudo first-order rate coefficient for deactivation of $\text{O}_2(^1\Delta)$ is 12 sec^{-1} , and the steady-state concentration of $\text{O}_2(^1\Delta)$ under the conditions just described is $3.6 \times 10^9/\text{cm}^3$.

More generally, we can express the steady-state concentration of $\text{O}_2(^1\Delta)$, in molecules/ cm^3 , in terms of the photon flux ϕ (as 10^{16} photons/ $\text{cm}^2\text{-sec}$) and the NO_2 concentration (in the common units of ppm) as

$$[\text{O}_2(^1\Delta)] = 2 \times 10^7(\text{NO}_2, \text{ppm})\phi \quad (4)$$

Under conditions of intense sunlight and moderately high concentrations of NO_2 , the steady-state concentration of

$\text{O}_2(^1\Delta)$ easily exceeds 10^7 cm^{-3} and may reach 10^8 cm^{-3} as a result of the NO_2 -activated mechanism alone. The concentration of O atoms is probably seldom greater than $5 \times 10^5 \text{ cm}^{-3}$ (Berry and Lehman, 1971) and may be up to an order of magnitude lower than this during earlier stages of the smog cycle (Johnston et al., 1971). It thus appears the NO_2 -activated mechanism by itself is capable of producing sufficient $\text{O}_2(^1\Delta)$ to make singlet molecular oxygen a contributor to smog formation despite the 10^3 – 10^4 -fold lower activity of the molecular species.

Early work on the photooxidation of hydrocarbons in the presence of NO_2 (Bufalini and Altshuller, 1967) indicated that the rate of hydrocarbon oxidation could be explained solely on the basis of O-atom oxidation. However, it should be noted that these experiments were conducted using uv light which photodissociates NO_2 to $\text{NO} + \text{O}$ quite efficiently and produces very little NO_2^* . Thus these early experiments were under conditions where $[\text{O}_2(^1\Delta)] \ll 10^4$ (O) and therefore have no bearing either positive or negative on the role of $\text{O}_2(^1\Delta)$ in the atmospheric oxidation of hydrocarbons.

In addition to the high NO_2 concentration experiments mentioned above, we have conducted experiments with the NO_2 concentration as low as 500 ppm and find the mechanism for $\text{O}_2(^1\Delta)$ formation remains operative. This strongly indicates that the energy transfer is truly an elementary molecular process and thus our extension to the atmosphere is valid.

After this work was submitted for publication, we learned that very similar conclusions have been reached by Jones and Bayes (1971) based on a very different detection method.

A more detailed discussion, including a study of the $^1\Sigma$ state, is in preparation.

Acknowledgment

We would like to thank Peter A. Lehman for his stimulating comments.
